

Distributed Shared Memory

see `field.c`

Distributed Shared Memory

Key problems:

- Sharing as transparently as possible
- Sharing as efficiently as possible

Sharing Changes

Most obvious idea: for each memory write or read, consult a central server

- Simple
- *Very* slow
- Difficult to make transparent

Sharing Changes

Better idea: check with central server at uses of synchronization abstractions

Based on the idea that changing shared data reliably requires synchronization

- Faster
- Still fairly simple
- Easier to make transparent

Sharing at Synchronization

```
    }  
sema_wait(s);  
a[2] = 7  
a[1] = a[2] + 3  
a[2] = a[1] + 2  
sema_post(s);
```

```
sema_wait(s);
```

```
a[1]++
```

```
...
```

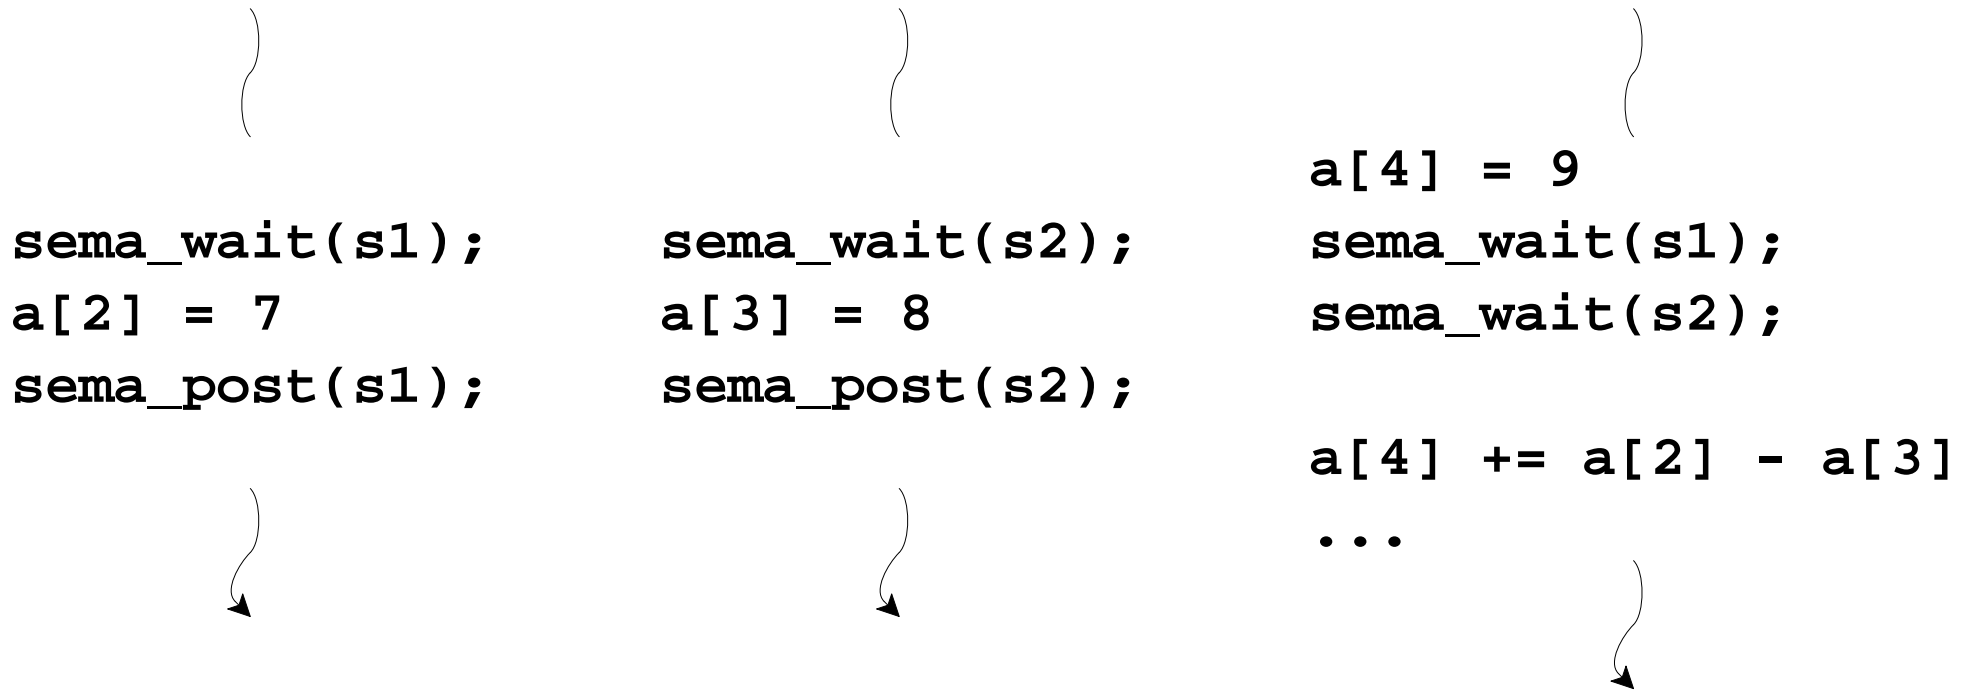

```
    }  
sema_wait(s);  
  
a[2] += 1  
a[1] = a[2] - 5  
sema_post(s);
```

```
...
```

Sharing at Synchronization

⇒ sites must track and communicate changes,
instead of whole memory

DSM State and Changes

Server tracks:

- Semaphore state
- Current memory state
- A per-site map of changes that need to be sent

Client tracks:

- State most recently received from server
 - Can be compared to current local state to generate a change map

DSM State Communication

Client grabs a lock:

- Get state changes from the server right after

Client releases a lock:

- Send changes since last communication right before

Mini-DSM

see `network_dsm_client.c`,
`network_dsm_server.c`

Improving DSM

Sending/receiving global state updates is slow and usually unnecessary

Checking all memory to detect changes is slow and usually unnecessary

Alternatives:

- Use pages and page protection to transparently detect changes and accesses

`see network_page_dsm_client.c`

- Put all state in objects, and let the object accessors and mutators communicate with the server as needed
